Abstract

Full Dimension multiple input multiple output (FD-MIMO) architecture employs a planar array design at the Base Station (BS) to provide high order multi-user MIMO (MU-MIMO) via simultaneous data transmission to large number of users. With FD-MIMO, the BS can also adjust the beam direction in both elevation and azimuth direction to concentrate the energy on the user of interests while minimizing the interference leakage to co-scheduled users in the same cell or users in the neighboring cells. In a typical highly populated macrocell environment, modelling the elevation angular characteristics of three-dimensional (3D) channel is critical to understanding the performance limits of the FD-MIMO system. In this paper, we study the throughput performance of FD-MIMO system with varying elevation angular spread and inter-element spacing using a 3D spatial channel model. Our results show that for a typical urban scenario, horizontal beamforming with correlated antenna spacing achieves optimal performance but by restricting the spread of elevation angles of departure, elevation beamforming achieves high array gain with wide inter-element spacing. We also realize significant gains due to spatial array processing via modelling the elevation domain and varying the inter-element spacing for both the transmitter and receiver.

Keywords: FD-MIMO, 3D spatial channel model, urban channel model, inter-element spacing, and elevation angles of departure restriction.

This work was partly supported by Institute for Information & communications Technology Promotion(IITP) grant funded by the Korea government(MSIP) (No.B0722-16-0006,Cross Layer Design of Cryptography and Physical Layer Security for IoT Networks) and the Basic Science Research Program through the National Research Foundation of Korea funded by the Ministry of Science, ICT and Future Planning under Grant NRF-2016R1C1B2011921.

1. Introduction

There is an exponential rise in the demand of high data rates driven by the corresponding rise in affordable smartphones, the availability of cloud-based services and the many new connected devices on the market [1]. Research in [1] shows that with the current trend in wireless data demand, urban areas are expected to generate up to 60% of total mobile traffic. Thus there is the need to develop technologies which can guarantee improved user experience via higher network coverage. In June 2012, technologies including full dimension multiple input multiple output (FD-MIMO) and user specific beamforming was identified by the 3rd Generation Partnership Project (3GPP) as potential means of providing the required data capacity and spectral efficiency for next generation wireless networks.

FD-MIMO is an extension of massive MIMO [2] where a few hundreds of antennas are deployed at a base station (BS) to simultaneously support tens of users on the same time-frequency resource. It uses a 2-dimensional (2D) active antenna and other advanced signal processing techniques at the BS to improve the data capacity. It can achieve multi-user array gain of high order with the provision of effective data transmission to a large number of users in the network simultaneously. The work of [3] has shown that vertical deployment of antenna at the BS allows the utilization of the elevation domain and can provide up to 30% gain.

Research by [4], [5], [6] provides fundamental understanding on the benefits of FD-MIMO. It proved that using large planar array at the BS can achieve high order multiuser gain from high number of antennas, although it would limit the effective spacing between different antenna elements compared to conventional linear array. Also by varying the user density in the simulated network, 2-5 times cell average improvement is observed in [7]. The work of [7] also explored other challenges in implementing FD-MIMO including downlink precoding, channel quality indicator prediction and antenna virtualization. Ioannis et al [8], discussed the architecture of 2D antenna array and also port virtualization techniques which is used to create beams with wide coverage, necessary for broadcasting signals to all users within a sector. Most results thus far focused on beamforming techniques and 3D channel modelling.

Our previous work [9] explores the optimal antenna element arrangement which could harness the benefits of FD-MIMO by modelling only the elevation spread. We have shown that for equal spacing, square uniform planar array provides optimal performance in an urban macrocell environment. Recently, field trials of the proof-of-concept FD-MIMO systems have been conducted successfully [10]. In order to study performance evaluation of FD-MIMO, the problem of modelling the elevation spread in 3D channel is of prime importance. Previously the channel model considers the departure and arrival of multipath components in the azimuth angles only. So far elevation angle of 3D antenna arrays has been considered for different scenarios in 3GPP [11] however no complete channel model has been developed for realistic systems, hence more measurements have to be carried out. Also the available 2D channel models proposed in [12] and International Telecommunication Union (ITU) [13] are insufficient to study and completely evaluate the planar array performance.

In our research, we implement a complete 3D channel model by extending the azimuth channel statistics of the Spatial Channel Model (SCM) [14] to the elevation dimension. Our 3D SCM is then validated through extensive simulations to examine some bulk parameters

that describe the characteristics of the channel over larger areas of several wavelengths. The architecture of the transmitter in FD-MIMO is very important as it dictates the potential gain of the system. So we study the effect of different transmitter and receiver antenna configuration on the performance of FD-MIMO system. By spacing the antenna elements sufficiently apart, it is possible for the signals received at these elements to undergo such a scattering in the propagation environment leading to either high or low correlation and thus resulting in high or low array gain respectively.

Our work introduces elevation angles of departure (eAoDs) restriction to perfectly model far-field scattering characteristics since BS antennas are well located above rooftops and as such there is no significant scattering around the BS. This also models the effect of NLOS dominance in typical urban environment. We then evaluated via sum-rate calculations, the best antenna configuration which could harness the high gain benefits of FD-MIMO taking the inter-element spacing and elevation angular spread into consideration. Results in this paper show that horizontal 16-by-1 antenna array with correlated antenna spacing provides very good performance for the typical urban case while 1-by-16 antenna array with wider spacing provides the best performance for urban channel with elevation spread limitation. The reverse results are obtained for the cell edge performance.

This paper is organized as follows; Section II introduces the FD-MIMO system model including the experimental set-up and the 3D channel model. Section III discusses an overview of beamforming in FD-MIMO and also the multi-user scheduling technique. Simulation environment and parameters, performance analysis of the FD-MIMO system are presented in Section IV. We present our conclusion in section V.

2. 3D Multicell Model

2.1 Transmission model

The transmission technique employed in this paper follows the multi-user space-division multiple access (SDMA) similar to that used in LTE-A systems as depicted in Fig. 1. It generally operates on a two-steps procedure described as follows;

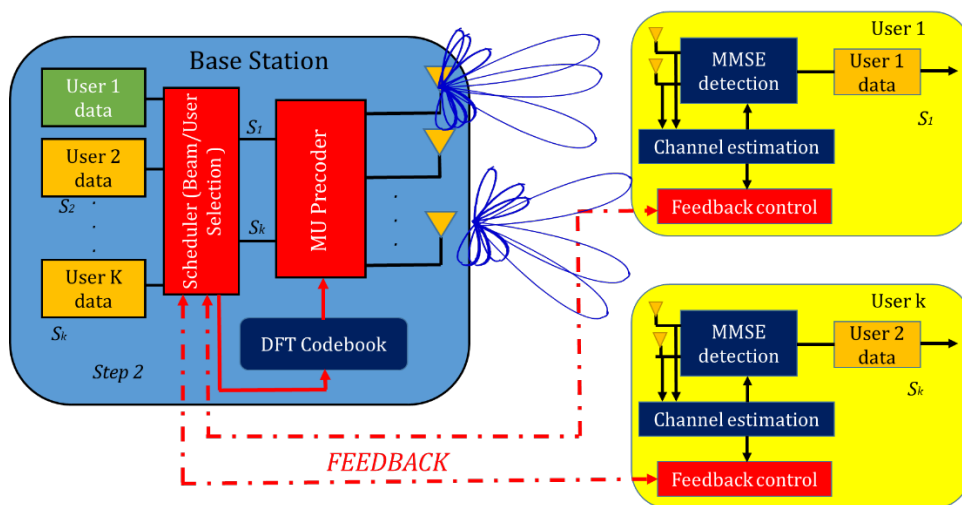

Fig. 1. Schematic illustration of the Transmission Model

Step 1: the user in the network determines the preferred precoding matrix from the shared codebook, the post-processing signal-to-interference-ratio (SINR) and the preferred number of transmitted spatial layers periodically, then reports the rank indicator (RI), the channel quality indicator (CQI) and the precoding matrix indicator (PMI) to the serving BS by means of feedback. The PMI signals codebook index of the preferred precoding matrix and RI informs the transmitter about the number of useful spatial transmission layers for the current MIMO channel. Step 2: The base station selects the precoding matrix and the number of transmission signals based on the PMI and RI feedback for independent users. The Base station then schedules a user using a scheduling and user pairing algorithm in order to efficiently utilize the system resources. A sound methodology consisting of the cellular model, channel model and the procedure of simulation is required for the fair evaluation of proposed wireless technologies. The simulation method for evaluating the transmission system in Fig. 1 is described by the algorithm in Fig. 2 [15]. The complete system level model in Fig. 2, defines a number of ‘drops’ where a mobile is placed in a sequence of different network locations. This also represents a snapshot of the fading channel.

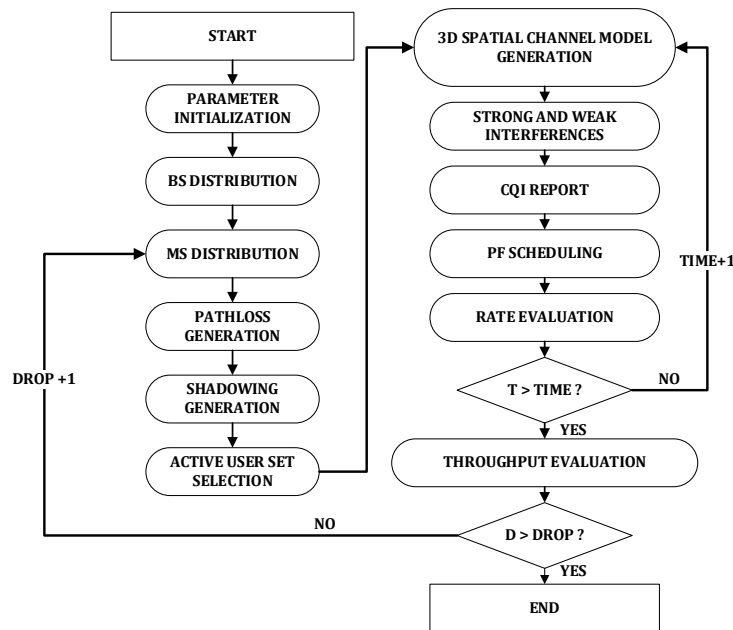

Fig. 2. System level simulation implementation

2.2 System Model

Our channel assumption models a typical high rise urban macro-cell scenario with line-of-sight (LOS) and Non-line-of-sight (NLOS) conditions. Users are assumed to be at street level and fixed base stations clearly above the average surrounding building heights. We consider a MIMO downlink transmission consisting of B base stations and K multi-antenna mobile stations in a typical homogeneous cellular network consisting of 57 cells in a two-tier deployment with a minimum inter-site distance of 500 m. Additionally users are assumed to be randomly distributed. The b -th base station is equipped with N_T ($N_V \times N_H$) transmit

antennas and sends independent information to its associated MSs denoted by $k \in \{1, \dots, K\}$ each equipped with N_R antennas. N_V represents the elements in the vertical dimension while N_H represents the elements in the horizontal domain.

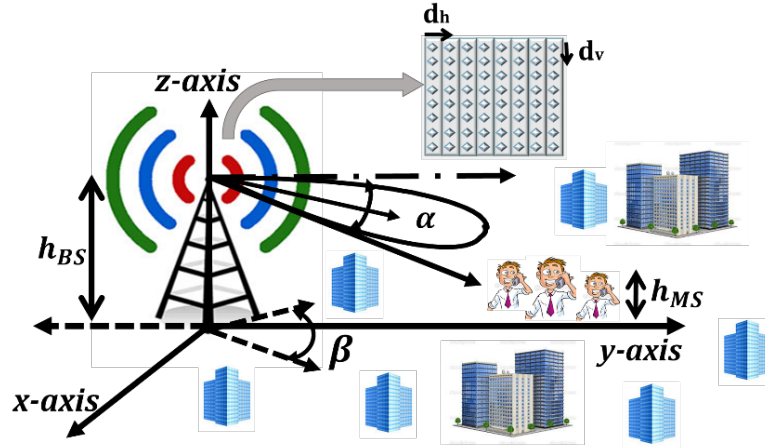

Fig. 3. Schematic illustration of the channel model

The maximum signal-strength cell association scheme is implemented such that users associate with the closest BS having the highest received power based on pathloss and shadowing [14]. We use the following notations throughout the paper: \mathbf{A}^H represents the conjugate transpose of a matrix \mathbf{A} , \mathbf{A}^{-1} the inverse of a matrix \mathbf{A} and \mathbf{A}^T represents the transpose of a matrix \mathbf{A} . We implement an SDMA system which constructs a total of $N_T - 1$ orthonormal beams which transmits to N_T users $\{k_p\}_{p=0, \dots, N_T-1}$ by means of precoding vector $\{\mathbf{w}_p \in \mathbb{C}^{N_T \times 1}\}_{p=0, \dots, N_T-1}$. The precoded transmission signal $\mathbf{x} \in \mathbb{C}^{N_T \times 1}$ is given as

$$\mathbf{x} = \mathbf{W}\mathbf{s} = \sum_{p=0}^{N_T-1} \mathbf{w}_p s_p \quad (1)$$

where $\mathbf{W} = [\mathbf{w}_0, \mathbf{w}_1, \dots, \mathbf{w}_{N_T-1}] \in \mathbb{C}^{N_T \times N_T}$ and $\mathbf{s} = [s_0, s_1, \dots, s_{N_T-1}]^T$ is the uncoded symbol vector with $E\{|s|^2\} = P_T$. We assume the total transmit power P_T is equally allocated over N_T scheduled users. The selection of $N_T - 1$ precoding vectors are based on a beam-and-user-selection algorithm described in section 3.2. We also assume a frequency-flat block fading channel from the target BS to the k -th user. The received signal vector of the k -th user at the b -th base station, $y_{k;b} \in \mathbb{C}^{N_R \times 1}$ is given as [16];

$$y_{k;b} = \sqrt{\frac{P_T}{N_T}} \sum_{i=1}^B \mathbf{H}_{k;b,i} \sum_{j=1}^{N_T} \mathbf{x}_{j;i} + \mathbf{c}_{k;b} \quad (2)$$

$$y_{k;b} = \sqrt{\frac{P_T}{N_T}} \left(\mathbf{H}_{k;b,b} \mathbf{w}_{k;b} s_{k;b} + \underbrace{\sum_{k' \neq k} \mathbf{H}_{k;b,b} \mathbf{w}_{k';b} s_{k';b}}_{\text{intracell interference}} \right) + \underbrace{\sum_{i' \neq b} \sum_{j=1}^{N_T} \sqrt{\frac{P_T}{N_T}} \mathbf{H}_{k;b,i'} \mathbf{w}_{j;i'} s_{j;i'}}_{\text{intercell interference}} + \mathbf{c}_{k;b} \quad (3)$$

where $\mathbf{H}_{k;b}$ is an $N_R \times N_T$ complex channel matrix between the k -th user at the b -th base station and $\mathbf{c}_{k;b} \in N_R \times 1$ is a zero mean spatially white complex Gaussian receiver noise vector of covariance matrix $C_o \mathbf{I}_{N_R}$. Each user symbol $\{s_p\}_{p=0, \dots, N_T-1}$ is recovered at the corresponding users via a minimum mean square error (MMSE) detection [17]. The SINR γ_{k,N_T} on the $(N_T - 1)$ -th stream of the k -th receiver is given by

$$\gamma_{k,N_T} = \mathbf{w}_{k;b}^H \mathbf{H}_{k;b}^H \left(\begin{array}{c} C_o \mathbf{I}_{N_R} + \\ \sum_{k'=1, k' \neq k}^{N_T} \mathbf{H}_{k';b} \mathbf{w}_{k';b} \mathbf{w}_{k';b}^H \mathbf{H}_{k';b}^H + \\ \sum_{b'=1, b' \neq b}^B \mathbf{H}_{k;b'} \mathbf{W} \mathbf{W}^H \mathbf{H}_{k;b'}^H \end{array} \right)^{-1} \mathbf{H}_{k;b} \mathbf{w}_{k;b} \quad (4)$$

To accurately model the azimuth and elevation angle of the 3D channel [18], we used the 3D coordinate system represented in Fig. 3. Let x_b, y_b, z_b be the coordinates of the serving 3D MIMO BS, where x_b, y_b, z_b are the values of the x-coordinates, y-coordinates and z-coordinates respectively. A similar approach i.e. $(x_{k;b}, y_{k;b}, z_{k;b})$ can be used to describe the position of the MS with respect to the BS. For convenience purposes, we define $\Delta x = x_b - x_{k;b}$, $\Delta y = y_b - y_{k;b}$, $\Delta z = z_b - z_{k;b}$ as the difference of the various coordinates between the b -th BS and the users. From this we can determine theoretically the distance between the BS and all the users as well as the corresponding azimuth and elevation angles as;

$$d_{k;b} = \sqrt{(\Delta x)^2 + (\Delta y)^2 + (\Delta z)^2} \quad (5)$$

$$\beta = \text{atan2}(\Delta y, \Delta x) \quad (6)$$

$$\alpha = \text{atan2}(\Delta z, \sqrt{(\Delta x)^2 + (\Delta y)^2}) \quad (7)$$

The antenna gain which is a necessary factor to determine the large scale fading and can be determined by [19], [20];

$$A_V(\alpha) = -\min \left[12 \left(\frac{\alpha - \alpha_{\text{tilt}}}{\alpha_{3dB}} \right)^2, A_m \right] \quad (8)$$

$$A_H(\beta) = -\min \left[12 \left(\frac{\beta}{\beta_{3dB}} \right)^2, A_m \right] \quad (9)$$

where α is defined as the angle between the direction of interest and the boresight of the antenna in the vertical dimension, while β represents the same in horizontal domain. α_{3dB} and β_{3dB} are the 3dB beamwidth of the vertical and horizontal beam, respectively. $A_m = 20$ dB is the maximum attenuation while α_{tilt} is the electrical tilt angle. The 3D antenna gain is combined as a sum of horizontal and vertical antenna pattern gain and is given as

$$G(\alpha, \beta) = G_m - \min\{-[A_{E,V}(\alpha) + A_{E,H}(\beta)], A_m\} \quad (10)$$

Our simulator assumed $G_m = 14$ dB as the maximum directional antenna gain. Also mutual coupling among antenna elements is not considered. The macrocell distance-dependent pathloss is determined using the simplified COST231 Hata urban propagation model as reported in [14]. We adopt the log-normal shadowing model for the characterization of the shadowing effect in the 3D MIMO wireless channel.

2.3 3D Channel model

It has been established that optimal performance characteristics of FD-MIMO to a very large extent is dependent on the channel characteristics. Favorable channel or radio propagation environment is where the propagation channel responses between transmitter and all receivers are sufficiently different. Thus, it is important to accurately model the channel behavior to be close to realistic environment measurements to achieve the full potential of MIMO. The SCM was designed for evaluating multiple antenna systems and algorithms. The model was developed within a combined 3GPP-3GPP2 ad hoc group to address the need for a precise channel model able to facilitate fair comparisons of various MIMO proposals.

Fig. 4. 3D SCM Channel Model

The SCM specifies a set of paths between the BS and the users based on stochastic model of correlated random variables to establish the spatial, temporal and propagation characteristics for a particular channel realization. To completely understand the FD-MIMO system, it is important to model the 3D spatial channel. A simplified single-cluster illustration of the 3D SCM is shown in Fig. 4.

Currently 3GPP has developed some aspects of the 3D channel model and is in the process of finalizing the complete system. Since a detailed 3D SCM implementation is so far not available, we have constructed a working 3D SCM model by reusing the same modeling principle as the 2D SCM and by referring to the large scale fading statistics such as the elevation spread at departure, the elevation spread at arrival and the cross-correlations with other large scale fading parameters (when applicable) that are reported in [14],[21].

Fig. 5. Two (2)-Cluster SCM for Elevation dimension

Fig. 5, shows a two-cluster SCM channel for the elevation domain. From this figure we can define the absolute angles of departure and arrival for both the elevation and azimuth as;

$$\alpha_{n,m,EAoD} = \alpha + \delta_{n,EAoD} + \Delta_{n,m,EAoD} \quad (11)$$

$$\theta_{n,m,EAoA} = \theta + \delta_{n,EAoA} + \Delta_{n,m,EAoA} \quad (12)$$

$$\beta_{n,m,AAoD} = \beta + \delta_{n,AAoD} + \Delta_{n,m,AAoD} \quad (13)$$

$$\varphi_{n,m,AAoA} = \varphi + \delta_{n,AAoA} + \Delta_{n,m,AAoA} \quad (14)$$

It is important to note that, the subpath angle offsets are taken from Table 5.2 in [14] and are such that;

$$\Delta_{n,m,EAoD} = \Delta_{n,m,AAoD} = \Delta_{n,m,AoD} \quad (15)$$

$$\Delta_{n,m,EAoA} = \Delta_{n,m,AAoA} = \Delta_{n,m,AoA} \quad (16)$$

In our work we introduce a parameter known as the range restriction factor based on results from popular channel measurements which would model the EAoD restriction used in our work. Thus all BS EAoDs are limited to the ranges in Table 1 for each channel environment.

Table 1. Environment Elevation Range Spread

Channel	Elevation Range Spread $\Omega_r = \{(-\alpha^\circ) \sim (+\alpha^\circ)\}$
General Urban NLOS channel	$-180^\circ \sim 180^\circ$
Urban NLOS channel with EAoD restriction	$-10^\circ \sim 10^\circ$
Urban LOS channel	0°

In the case of LOS urban channel; the elevation AoD restricted to single direction (in this case 0°). This is due to the fact that from channel measurements we note that $\theta > 90^\circ$ is rarely observed, therefore we restricted the elevation AoD range to $[-10^\circ, 10^\circ]$ with respect to the LOS path between the two terminals. Also all AoDs outside the restricted angular zone is set to the LOS which in this case is 0° . Thus majority of all AoDs would be in the LOS

direction. The fading processes for each sector and receive antenna are independent, and the doppler rate is determined by the speed of the users. We assume that the fading is equivalent for each mobile receive antenna. These assumptions are feasible and consistent with practical channel measurements recorded in literature. The overall procedure for generating the channel matrices [14] as shown in Fig. 6 consists of three basic steps:

- i. Selecting environment, either general urban NLOS, urban NLOS with elevation restriction, or urban LOS
- ii. Obtain the parameters to be used in simulations, associated with that environment
- iii. Generate the channel coefficients based on the parameters generated.

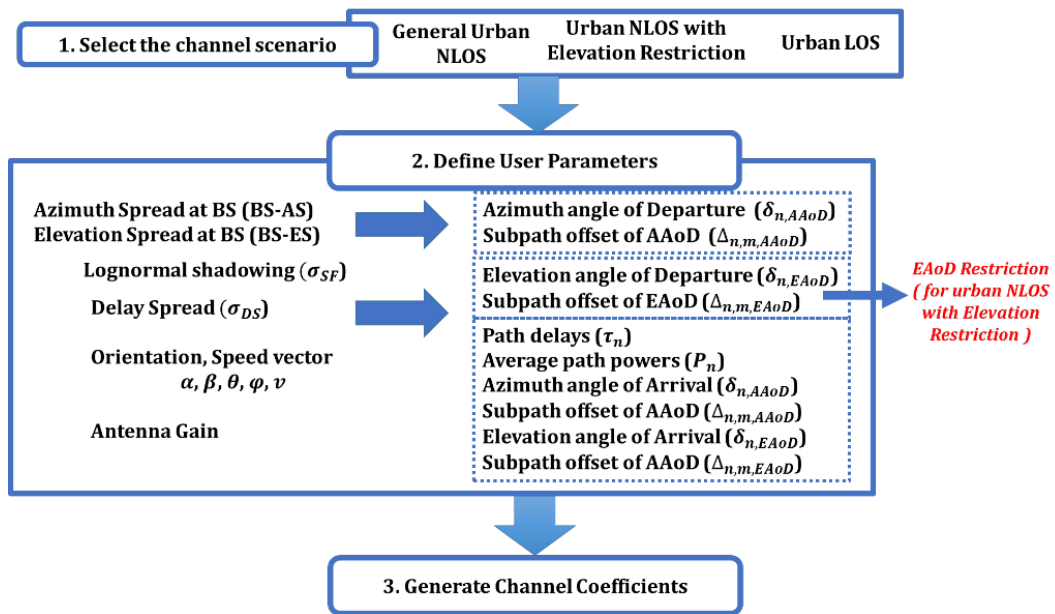

Fig. 6. Channel model overview for simulations

The channel of the n -th path between the u -th MS antenna and s -th BS antenna is given by

$$h_{u,s,k} = \sqrt{\frac{p_n \sigma_{SF}}{M}} \sum_{m=1}^M \begin{bmatrix} \sqrt{G_{BS}(\alpha_{n,m,AoD}, \beta_{n,m,AoD})} \times \\ \exp(j[kd_s \bar{r}_s \overline{\Phi_{n,m}} + \Phi_{n,m}]) \times \\ \sqrt{G_{MS}(\theta_{n,m,AoA}, \varphi_{n,m,AoA})} \times \\ \exp(j[kd_u \sin(\theta_{n,m,AoA})]) \times \\ \exp\left(j \left[k \|\mathbf{v}\| \cos \varphi_{n,m,AoA} \times \right. \right. \\ \left. \left. \cos(\theta_{n,m,AoA} - \theta_v) t \right] \right) \end{bmatrix} \quad (17)$$

where

$$\bar{r}_s \overline{\Phi_{n,m}} = x_s \cos \beta_{n,m,AoD} \cos \alpha_{n,m,AoD} +$$

$$y_s \cos \beta_{n,m,AoD} \sin \alpha_{n,m,AoD} + z_s \sin \beta_{n,m,AoD} \quad (18)$$

For the purposes of our simulation, we assume the elevation angular spread for typical urban macrocell case ranges from $0 \leq \theta \leq 360^\circ$. The notations used in the above equation are defined in **Table 2** below;

Table 2. Parameter definitions

Parameter	Representation
p_n	The power of the n -th path
σ_{SF}	The lognormal shadow fading, applied as a bulk parameter to the N paths for a given drop
$\beta_{n,m,AAoD}$	Elevation domain angle of departure (EAoD) for the m -th subpath of the n -th path at the BS with respect to the BS broadside
$\varphi_{n,m,AAoA}$	Elevation domain angle of departure (EAoD) for the m -th subpath of the n -th path at the BS with respect to the BS broadside
$\alpha_{n,m,EAoD}$	Azimuth domain AoD (AAoD) for the m -th subpath of the n -th path at the BS with respect to the BS broadside
$\theta_{n,m,EAoA}$	Azimuth domain AoA (AAoA) for the m -th subpath of the n -th path at the MS with respect to the MS broadside
x_s, y_s, z_s	Components of $\bar{\mathbf{r}}_s$ to x , y , and z -axis respectively
$\bar{\mathbf{r}}_s$	Location vector of Tx array element s
d_u	The distance in meters from MS antenna element u from the reference ($u = 1$) antenna
d_s	The distance in meters from BS antenna element s from the reference ($s = 1$) antenna
$\bar{\Phi}_{n,m}$	Departure angle unit vector of ray n, m
$\Phi_{n,m}$	The random phase of the m th subpath of the n -th path
$G_{BS}(\cdot)$	The BS antenna gain of each array element
$G_{MS}(\cdot)$	The MS antenna gain of each array element
θ_v	The azimuth angle of the MS velocity vector with respect to the MS broadside
$\ \mathbf{v}\ $	The magnitude of the MS velocity vector
k	The wave number $\frac{2\pi}{\lambda}$ where λ is the carrier wavelength in meters

3. 3D MIMO Beamforming Technique

The Third Generation Partnership Project (3GPP) in release 12, focused on employing improved antenna structures to improve system performance through adaptive transmission in both elevation and azimuth dimension [22]. 3D beamforming exploits the 3D MIMO channel gains in the elevation dimension as well as the azimuth dimension providing additional degree of freedom as compared to the conventional 2D antenna beamforming [23]. Control of the elevation domain would allow the independent transmission of data to specific users thereby increasing the received SINR and also minimizing the interfering power from undesired sources [24]. This concept of beamforming is where an array of antennas is used to form one or several portions within a cell with controlled antenna radiation patterns. It is a signal processing technique which involves the application of weights to adjust the phase and

the amplitude of the transmit signals to form beam pattern towards the desired direction. This improves spectral efficiency and is especially good in cell edge user scenarios where signal power is low (i.e. low SINR).

3.1 Kronecker Product-Based Codebook

In order to fully exploit the performance gains of 3D MIMO employing frequency division duplexing, there is the need to design an optimal 3D codebook which takes the elevation channel state information into consideration. For highly correlated channel characteristics, the Discrete Fourier Transform (DFT)-based codebook has been proved to provide better performance in the case of both ULA and UPA. Due to its simplicity and effectiveness, it has been adopted by the 3GPP Long Term Evolution [25], [26]. The channels are highly correlated due to the fact that BS's with massive 3D antenna configuration tend to assemble large number of antennas within a limited space [27][28][29]. Thus the distances between the antennas become very small. Research in [30], showed that the correlation matrix of 3D channels can be approximated by the kronecker product of the azimuth and the elevation correlations. Using the idea of [30], [31] presented a MIMO feedback scheme based on the Kronecker product –based codebook. Basically the Kronecker product –based codebook is the product of two traditional discrete Fourier transform codebooks. The final codeword consists of the kronecker product of two oversampled DFT codewords from both the horizontal and vertical codebooks.

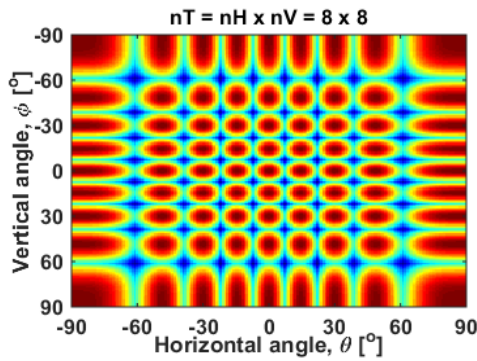

Fig. 7a. Beam pattern for 8X8 array

Fig. 7b. Beam pattern 16X4 array

In this design, the final codeword consists of the kronecker product of two oversampled DFT codewords from both the horizontal and vertical codebooks. Specifically $\mathbf{w} = (\mathbf{w}_1, \mathbf{w}_2, \dots, \mathbf{w}_{N_v \times N_h})$ is generated by

$$\mathbf{w}_{i,v} = \frac{1}{\sqrt{N_v}} \left[1, e^{\frac{j2\pi i}{N_v}}, \dots, e^{\frac{j2\pi(N_v-1)i}{N_v}} \right]^T \quad (19)$$

$$\mathbf{w}_{j,h} = \frac{1}{\sqrt{N_h}} \left[1, e^{\frac{j2\pi j}{N_h}}, \dots, e^{\frac{j2\pi(N_h-1)j}{N_h}} \right]^T \quad (20)$$

$$\mathbf{w}_{(i-1)N_v+j} = \mathbf{w}_{i,v} \otimes \mathbf{w}_{j,h} \quad (21)$$

where $i = 1, 2, \dots, N_v$; $j = 1, 2, \dots, N_h$; while N_v and N_h are the number of codewords in the horizontal and vertical codebook respectively and \otimes represents the kronecker product.

3.2 Multi-User Scheduling with Limited Feedback

Considering N_T column precoding vectors such that $\mathbf{W}_p = [\mathbf{w}_{p,1}, \mathbf{w}_{p,2}, \dots, \mathbf{w}_{p,N_T}] \in \mathbb{C}^{N_T \times N_T}$. Within the codebook, each selected precoding matrix corresponds to different receiver sets which directly affect the sum throughput [32][33]. Thus it is important to select an optimal precoding matrix and the corresponding user set which maximizes the data rate. This requires each user to feedback N_T sets of $N_T - 1$ signal to interference plus noise ratios $\{\gamma_{k,l}(\mathbf{W}_p)\}_{l=1, \dots, N_T, p=0, \dots, N_T-1}$. For the purposes of practicality, this SINR feedback method makes it possible to determine the optimal precoding matrix but the feedback overhead is prohibitive for implementation in an FD-MIMO system. The optimal scheme for practical implementation is the limited feedback scheme where each user only feedback N_T SINRs $\{\gamma_{k,l}(\mathbf{W}_{p_k})\}_{l=1, \dots, N_T}$ by selecting a precoding matrix \mathbf{W}_{p_k} within the shared codebook given that $p_k \in \{0, \dots, N_T - 1\}$. From our initial assumption that each user has perfect receiver CSI \mathbf{H}_k and also share the precoder codebook; the k -th user selects the precoding matrix as;

$$\mathbf{W}_{p_k} = \arg \max_{\mathbf{W}_p \in \mathbb{C}^{N_T \times N_T}} \max_{l=\{1, \dots, N_T\}} \gamma_{k,l}(\mathbf{W}_p) \quad (22)$$

We define $\gamma_{k,l}(\mathbf{W}_p)$ as the SINR on the l -th stream precoded by the \mathbf{W}_p of the k -th user defined using the MMSE receiver in (4). Since we assume the codebook $\{\mathbf{W}_p\}_{p=0, \dots, N_T-1}$ is known *a priori* to both the FD-MIMO BS and user, the user feeds back to the BS the index p_k and N_T SINRs $\{\gamma_{k,l}(\mathbf{W}_{p_k})\}_{l=1, \dots, N_T}$. All K users are then grouped into N_T groups based on their precoding matrix using the criteria

$$\Gamma_p = \{1 \leq k \leq K | p_k = p\}, 1 < p < N_T \quad (23)$$

Consequently the BS tries to assign $\mathbf{w}_{p,l}$ within each group to a user $k_{p,l}^*$ with the highest SINR obtained as $\gamma_{p,l}^* = \max_{k \in \Gamma_p} \gamma_{k,l}(\mathbf{W}_{p_k})$. The p^* -th precoding matrix \mathbf{W}_{p^*} used for the transmission is selected so as to optimize the instantaneous sum throughput as follows;

$$p^* = \arg \max_{p=0, \dots, N_T-1} \sum_{l=1}^{N_T} \log_2(1 + \gamma_{p,l}^*) \quad (24)$$

Therefore, the final set of scheduled users specified by the set of index $\{k_{p^*,l}^*\}_{l=1, \dots, N_T}$, share the p^* -th precoding matrix. This validates the information on user SINRs fed back to the BS and enables accurate prediction. The average sum throughput is given by

$$R = \sum_{l=1}^{N_T} \log_2(1 + \gamma_{p^*,l}^*) \quad (25)$$

3.3 SDMA Scheduling

The designated target sector assigns transmission resources and opportunities to selected users by using the channel quality information. The serving BS selects total users which are less than or equal to the number of transmit antennas and have the highest scheduling priority per transmit antenna [9], [18], [34]. Thus in the t -th time slot, the BS selects user using the proportional fair algorithm given as

$$k_{N_T}^* = \arg \max_{k \in \{1, 2, \dots, K\}} \frac{R_{k, N_T}}{\bar{R}_k} \quad (26)$$

where R_{k, N_T} is the instantaneous supported data rate for the k -th MS via N_T transmit antenna

while \bar{R}_k is the average data rate of the k-th user updated periodically as

$$\bar{R}_k(t+1) = \begin{cases} \left(1 - \frac{1}{t_c}\right)\bar{R}_k(t) + \frac{1}{t_c}R_{k,N_T}(t) & k = k_{N_T}^* \\ \left(1 - \frac{1}{t_c}\right)\bar{R}_k(t) & \text{otherwise} \end{cases} \quad (27)$$

We let the $\bar{R}_k(t)$ is data rate for the u -th user scheduled in the t -th time slot while t_c is the PF scheduler latency.

4. Simulation Results and Discussions

Using the system-level simulation techniques of the 3GPP LTE-A evaluation methodologies, the system sum-rate performance of the proposed FD-MIMO system is evaluated. Our system considered the typical urban macro deployment with varying number of transmitters and users as summarized in **Table 5**. The value of parameters employed in the generation of channel coefficients are also summarized in [4] and [14]. Performance of the system is measured with two metrics; cell average throughput which measures the overall system performance and the cell edge user throughput which represent the worst case UE performance. An antenna array configuration (H, V) corresponds to the horizontal and vertical elements whilst angular spread (AZ, EL) represents the angular spread in azimuth and elevation respectively. Our simulation assumes both the transmitter and receiver have full knowledge of the channel state information of the downlink channel. Also for simplicity, we assume all users are located at ground level (i.e. at 1.5m height).

Table 5. System Simulation Parameters

Parameter	Value
Multi-cell layout	19 cells each with 3 sectors in hexagon layout
Inter-BS site minimum distance	600 m (macro case)
Tx Power	43 dBm
Channel model	3D SCM
UE distribution	Uniform
UE speed	3 km/h
Scheduling delay	0ms
Channel estimation	Ideal without error
UE antenna number	2, 4, 8
Base Station antenna number	2, 4, 8, 16, 32, 64
Max antenna gain	14 dB
3 dB beamwidth	70 °(AZ), 23 °(EL)
Antenna element spacing	0.5λ, 1λ, 2λ, 4λ

4.1 Preliminary Results

Preliminary system-level simulation is conducted to evaluate the performance of FD-

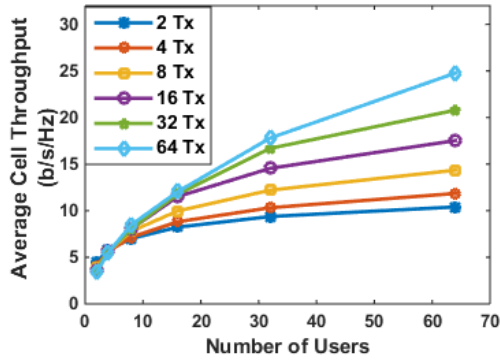

Fig. 8. Cell throughput for increasing users

Fig. 9. Cell edge throughput with increasing users

MIMO in terms of cell average performance and cell edge with increasing number of users. Results in Fig. 8 and Fig. 9 shows the effectiveness of massive MIMO in obtaining high data rates (improving the performance of both cell edge UE and the whole system) without sacrificing bandwidth. Cell edge performance is critical in addressing the performance of users at low SINR regions. This proves the theory that large number of base station antennas can remarkably improve performance data rate. With increasing number of antennas at the base station, the propagation channel potentially provides much more spatial selectivity, from which the system performance may be greatly improved. As is expected from Fig. 9 the increase in total number of users does not improve the cell edge performance; thus there is the need to increase transmit antennas for increasing number of users.

4.2 Throughput Performance for urban NLOS

Fig. 10. Urban NLOS Sum-rate performance for AZ 8° / EL 8°

Fig. 11. Urban NLOS Sum-rate performance for AZ 8° / EL 15°

Fig. 12. Urban NLOS Sum-rate performance for AZ 15° / EL 8°

Fig. 13. Urban NLOS Cell Edge Throughput for AZ 8° / EL 8°

Fig. 14. Urban NLOS Cell Edge Throughput for AZ 8° / EL 15°

Fig. 15. Urban NLOS Cell Edge Throughput for AZ 15° / EL 8°

As can be observed from Fig. 10-12, the overall performance is dominated by horizontal beamforming with $0.5\lambda/4\lambda$. This is because for horizontal antenna configuration with 0.5λ inter-element spacing, multi-user interference is minimized as the beamwidth formed by the DFT precoding is very narrow. The multi-user interference is also minimized due to the fact that for the azimuth domain with sufficient user distribution it is simple to identify sufficiently spaced users improving user and beam separability.

With the small range of elevation domain, there's high probability for strong multi-user interference due to low user separability. Also high inter-beam interference can minimize the expected array gain. It can also be observed that increasing the inter-element spacing for vertical beamforming can improve performance with 1x16 and 2x8. As can be observed in Fig. 13-15 for the cell edge scenario, vertical antenna configuration (1x16 and 2x8) with wide inter-element spacing (4λ) is optimal for all azimuth/elevation configurations. Improved performance is also observed with 8° elevation spread.

4.3 Throughput Performance for Urban NLOS with EAoD Restriction

From Fig. 13-15, due to the elevation AoD restriction, there is increased transmission of useful signals towards the user space. The elevation domain experiences very narrow beam with high directivity. The number of uniformly spaced antenna elements employed in beamforming is directly proportional to the beamwidth for a given steering angle. Thus with the increase in the number of transmitting beams in the elevation domain, beamwidth is minimized which minimized gain loss as a result of sector-to-sector interference.

Fig. 16. Urban Restriction Sum-rate performance for AZ 8° / EL 8°

Fig. 17. Urban Restriction Sum-rate performance for AZ 8° / EL 15°

Fig. 18. Urban Restriction Sum-rate performance for AZ 15° / EL 8°

Fig. 19. Urban Restriction Cell edge throughput for AZ 8° / EL 8°

Fig. 20. Urban Restriction Cell edge throughput for AZ 8° / EL 15°

Fig. 21. Urban Restriction Cell edge throughput for AZ 15° / EL 8°

The high directivity prevents losses due to inter-beam overlap. However horizontal beamforming with 16x1 with $4\lambda/4\lambda$ has the worst performance. The case of cell edge as observed in Fig. 19-21, horizontal beamforming 16x1 and 8x2 with $4\lambda/4\lambda$ and $4\lambda/0.5\lambda$ are the optimal antenna configuration for the azimuth/Elevation configuration. It can also be observed that varying the inter-element spacing in the elevation domain does not adversely affect sum-rate adversely; thus beamforming performs well both under correlated and uncorrelated inter-element spacing for the case of eAoD restriction.

4.4 Throughput Performance for Urban LOS

In the urban LOS scenario where elevation AoD restricted to single direction (in this case 0°), results obtained in Fig. 22-24 are similar to those obtained in the case of urban NLOS with eAoD restricted to $[-10^\circ, 10^\circ]$. Thus that vertical beamforming dominates performance for all inter-element spacing cases. This can be attributed to the elevation domain experiencing very narrow beam with high directivity as a result of the EAoD restriction. Elevation domain channel modelling through the restriction of AoDs maintains a strong spatial correlation with varying inter-element spacing.

An analysis of the results also shows that performance is large dependent on the varying inter-element spacing and the distribution of the AoDs and not necessarily the mean angular spread.

For cell edge throughput (Fig. 25-27), horizontal beamforming 16x1 and 8x2 with $4\lambda/4\lambda$ and $4\lambda/0.5\lambda$ respectively are the optimal antenna configuration for the azimuth/Elevation configuration as in the case of urban LOS. Vertical beamforming with 1x16 antenna configuration has the least performance due to the fact that narrow elevation beams are mostly directed towards MS's close to the cell center.

Fig. 28b. Optimal planar array pattern for urban with EAoD restriction (1x16 with $0.5\lambda/4\lambda$)

4.5 Throughput Performance with varying receiver inter-element spacing

We present analysis of the performance of our FD-MIMO system with varying transmit and receiver antennas. The various transmit/receive architecture presented in the results are shown in **Table 5** below. From **Fig. 29** with the elevation angle of departure restriction, 2x4 correlated transmit antennas and 4 correlated receive antennas outperforms other configurations. For the case of no elevation restriction in **Fig. 30**, optimal configuration is observed for increased receiver antenna i.e. 2X2 (0.5λ) / 8 (0.5λ).

Comparatively, improved throughput performance is obtained with increased MS antennas for typical urban NLOS case. Due to MS antenna design restriction, increasing the number of BS antenna elements with correlated inter-element spacing is sure to provide optimal performance.

Table 5. Results for Varying Tx/Rx Structure

Case	Tx / Rx Structure	Case	Tx / Rx Structure
A	4X4 (0.5λ) / 2 (0.5λ)	G	2X2 (0.5λ) / 8 (0.5λ)
B	4X4 (0.5λ) / 2 (2.0λ)	H	2X2 (2.0λ) / 8 (0.5λ)
C	4X4 (1.0λ) / 2 (4.0λ)	I	2X2 (4.0λ) / 8 (0.5λ)
D	2X4 (0.5λ) / 4 (0.5λ)	J	4X2 (0.5λ) / 4 (0.5λ)
E	2X4 (0.5λ) / 4 (1.0λ)	K	4X2 (0.5λ) / 4 (1.0λ)
F	2X4 (1.0λ) / 4 (2.0λ)	L	4X2 (1.0λ) / 4 (2.0λ)

5. CONCLUSION

In this paper we analyse the sum-rate performance of practical planar array configuration for FD-MIMO in urban 3D environment using system level simulations. Typically MU-MIMO with 3D beamforming can work well in both correlated and uncorrelated antenna structures but for the case of urban macrocell channel with users located at street level, cell average performance is optimal with horizontal linear array with small inter-element spacing (0.5λ). By assuming zero mutual coupling effect between antenna elements, half-wavelength spacing would be the ideal choice to maintain high spatial correlation without greatly increasing the physical dimensions of the array. By restricting the elevation angles of departure, higher array gain is obtained via wide elevation inter-element spacing. The performance trend for cell edge is opposite as typical urban supports high cell edge throughput with vertical antenna beamforming whilst for the case or restriction, horizontal antenna beamforming is optimal. In designing the transmit grid of beams for FD-MIMO, it is important to design the antenna array and choose optimal configurations including inter-element spacing for different angular spread scenarios since performance is sensitive to interference. Results in [5],[6],[7],[8] and [35] shows that for small angular spread value (typically a fixed value), the azimuth beamforming performs better than the elevation. It was proposed in [4-8] that an increase in the angular spread and inter-element spacing in the elevation domain would increase the elevation beamforming gain. Our work tested varying angular spread and inter-element spacing for both horizontal and vertical domain. We observed a similar pattern where the increase in the angular spread and elevation inter-element spacing increasing the beamforming gain. Table 6 presents a summary of the results discussed in this paper.

Table 6. Summary of Results

Channel Model	Cell Average Throughput (b/s/Hz)			Cell Edge Throughput (b/s/Hz)		
	Angular Spread Variations (AZ / EL)			Angular Spread Variations (AZ / EL)		
	8° / 8°	8° / 15°	15° / 8°	8° / 8°	8° / 15°	15° / 8°
Urban NLOS	16X1 (0.5λ/4λ)	16X1 (0.5λ/4λ)	16X1 (0.5λ/4λ)	2X8 (0.5λ/4λ)	2X8 (0.5λ/4λ)	1X16 (4λ/4λ)
Urban NLOS with Restriction	1X16 (0.5λ/4λ)	1X16 (0.5λ/4λ)	1X16 (0.5λ/4λ)	8X2 (4λ/0.5λ)	8X2 (4λ/0.5λ)	8X2 (4λ/4λ)
Urban LOS	1X16 (4λ/4λ)	1X16 (4λ/4λ)	1X16 (4λ/4λ)	16X1 (4λ/4λ)	8X2 (4λ/0.5λ)	8X2 (4λ/0.5λ)

Alidu Abubakari received the B.S. degree in telecommunication engineering from the Kwame Nkrumah University of Science and Technology, Kumasi, Ghana, in 2013, and the M.S. degree in electronic engineering from Hanbat National University, Daejeon, South Korea, in 2016 where he is pursuing a Ph.D. degree in electronic engineering. He is currently a Researcher in substation automation and smart grid communication at Korea Electric Power Company, Daejeon, South Korea. His research interests include distributed massive MIMO networks (3-D spatial channel modeling, beamforming, and SDMA), cloud radio access networks, small cells, smart grid and heterogeneous networks.

Sabogu-Sumah Raymond was born in Ghana. He received the B.Sc. degree in telecommunications engineering (First Class Hons) from the Kwame Nkrumah University of Science and Technology, Kumasi, Ghana, in 2013. He is currently pursuing the master's degree with Hanbat National University, Daejeon, South Korea. He was with Huawei Technologies and National Communications Authority both in Ghana as a Network Optimization and Telecommunications Engineer, respectively. His research interests include spectrum sharing, coexistence between wireless services, millimeter wave communications, and cognitive radio networks.

Han-Shin Jo received the B.S., M.S., and Ph.D. degrees in electrical and electronics engineering from Yonsei University, Seoul, South Korea, in 2001, 2004, and 2009, respectively. He is currently an associate Professor with the Department of Electronics and Control Engineering, Hanbat National University, Daejeon, South Korea. He was a Post-Doctoral Research Fellow with the Wireless Network and Communications Group, Department of Electrical and Computer Engineering, University of Texas at Austin, from 2009 to 2011. He developed a long-term evolution base station in Samsung Electronics from 2011 to 2012. His current research interests are in all the aspects of MIMO (channel modeling, precoding and scheduling with limited feedback, beamforming, SDMA, and massive MIMO) and applications of stochastic geometry and optimization theory to wireless cellular and ad hoc networks. He received the Samsung Electronics Graduate Fellowship from 2006 to 2008, the Korea Research Foundation BrainKorea21 Graduate Fellowship from 2006 to 2007, the Korea Research Foundation Post-Doctoral Fellowship in 2009, and the 2011 ETRI Journal Best Paper Award.
